**Abstract**—General Video Game Playing (GVGP) allows for the fair evaluation of algorithms and agents, as it minimizes the ability of an agent to exploit apriori knowledge in the form of game specific heuristics. In this paper we compare four possible combinations of evolutionary learning, using Separable Natural Evolution Strategies as our evolutionary algorithm of choice; linear function approximation with *Softmax* search and  $\epsilon$ -greedy policies and neural networks with the same policies. The algorithms explored in this research play each one of the games during a sequence of 1000 matches, where the score obtained is used as a measurement of performance. We show that learning is achieved in 8 out of the 10 games employed in this research, without introducing any domain specific knowledge, leading the algorithms to maximize the average score as the number of games played increases.

## I. INTRODUCTION

Learning how to act in unknown environments is often termed the “Reinforcement Learning” problem [1]. The problem encapsulates the core of artificial intelligence and has been studied widely under different contexts. Broadly speaking, an agent tries to maximize some long term notion of utility or reward by selecting appropriate actions at each state. Classic RL assumes that state can somehow be identified by the agent in a unique fashion, but it is often the case that function approximators are used to help with state spaces that cannot be enumerated.

A possible way of attacking the problem in the general sense is Neuroevolution (for an example use in games see [2]). Neuroevolution adapts the weights of a local or global function approximator (in the form of a neural network) in order to maximize reward. The appeal of neuroevolution over traditional gradient-based Reinforcement learning methods is three-fold. First, the gradient in RL problems might be unstable and/or hard to approximate, thus requiring extensive hyper-parameter tuning in order to get any performance. Secondly, the tournament-ranking schemes used by evolutionary approaches are robust to outliers, as they are effectively calculations of medians rather than means. Thirdly, classic RL algorithms (at least their critic-only versions [3]) can be greatly impacted by the lack of a perfect markov state. Sensor aliasing is a known and common problem in RL under function approximation.

On the other hand the lack of direct gradient information limits the possible size of the parameters of the function approximator to be evolved. If provided with the correct setup and hyperparameters, RL algorithms might be able to perform at superhuman level in a number of hard problems. In practical terms, research into RL has often been coupled with the use of strong heuristics. General Game Playing allows for completely arbitrary games, making the easy application of temporal based

methods non-trivial. On the other hand, modern evolutionary algorithms require minimum fine-tuning and can help greatly with providing a quick baseline. In this paper we perform experiments using evolutionary algorithms to learn actors in the following setup.

Among evolutionary algorithms, for problems with continuous state variables, a simple yet robust algorithm is Separable Natural Evolution Strategies (S-NES) [4]. Coupling the algorithm with different policy schemes and different approximators yields the experimental methods:

- S-NES using  $\epsilon$ -greedy policy and linear function approximator
- S-NES using  $\epsilon$ -greedy policy and neural network
- S-NES using softmax policy and a linear function approximator
- S-NES using softmax policy and a neural network

We will see specifics of this setup in later sections. In order to make this research easy to replicate and interesting in its own right, the environmental substrate is provided by the new track of the General Game Playing AI Competition. We evaluate our players in this setup.

The paper is structured as follows: Section II does a brief review of the current state of the art in General Game Playing. Section III describes the framework used in this paper for evaluating games. We describe the algorithms used in Section IV, while in Section V we present the experimental results. We conclude with a small discussion in Section VI.

## II. RELATED RESEARCH

While there has been considerable research in the topic of both Neuroevolution and General Game Playing (GGP). GGP [5] was initially mostly concerned with approaches that included access to a forward model, i.e. agents/players have the ability to predict the future to a certain extent and plan their actions, with domains that are more closely aligned to board games and are deterministic. Recently, a competition termed “The general video game playing competition” [6] has focused on similar problems, but this time in the real-time game domain. The competition provided the competitors with internal models they could sample from (but not access to specific future event probabilities), while limiting the amount of “thinking” time provided for an agent to 40ms (imposing an-almost-real-time constraint). In both contexts, algorithms that dominated were sample based search methods [?], [6], also known as Monte Carlo Tree Search. In the case of GVG-AI [6], which allows for stochastic environments, open loop monte-carlo tree search methods seem to perform best.

There has also been considerable effort in learning how to play games in a generic fashion outside competitions, using the Atari framework [7], which provides a multitude of games for testing. The games were attacked recently [8] using a combination of neural networks and Q-learning with experience replay. The method was widely seen as a success (though it could still not outperform humans in all games). The methods for these games operate on a pixel level and require a significant amount of training, but the results achieved when successful cover the full AI loop (from vision to actions).

Neuroevolution has been used for real time video games [2], General Game Playing see [9] and playing Atari games [10], with varying degrees of success. In the front of solving Atari games, Neuroevolution showed strong results using NEAT [?], a method that evolves all network parameters (including the topology of the network).

### III. THE GVGAI FRAMEWORK

#### A. The framework

The General Video Game Playing competition and framework (GVG-AI) is built on VGDL (Video Game Description Language), a framework designed by Ebner et al. [11] and developed by Tom Schaul [12] for GVGP in Python (*py-vgdl*). In VGDL, there are several *objects* that interact in a two-dimensional rectangular space, with associated coordinates, with the possibility of moving and colliding with each other. VGDL defines an ontology that allows the generation of real-time games and levels with simple text files.

The GVG-AI framework is a Java port of *py-vgdl*, re-engineered for the GVG-AI Competition by Perez et al. [6], which exposes an interface that allows the implementation of controllers that must determine the actions of the player (also referred to as the *avatar*). The VGDL definition of the game is **not** provided, so it is the responsibility of the agent to determine the nature of the game and the actions needed to achieve victory.

The original version of this framework provided a *forward model*, that allowed the agent to simulate actions on the current state to devise the consequences of the available actions. In this case, the agents counted on 40ms of CPU time to decide an action on each game cycle. This version of the framework was employed by the organizers of the competition to run what is now called the “planning track” of the contest, celebrated on the Computational Intelligence in Games (CIG) conference in Dortmund (Germany) in 2014. A complete description of this competition, framework, rules, entries and results has been published in [6].

2015 will feature a new track for this competition, named “learning track”. In this track, controllers do **not** have access to forward model, so they cannot foresee the states reached after applying any of the available actions of the game. In contrast, they will be offered with the possibility of playing the game many times, with the aim of allowing the agents to learn how to play each given game.

Information is given regarding the state of the game to the controllers, at three different stages: initialization, at each game step (*act* call, called repeatedly, until the game is finished) and

termination. Table I summarizes the information given to the agent and at which stages this is passed.

#### B. Games

The games employed for this research are the ones from the training set of the GVG-AI competition. These games are described in detail here:

1) *Aliens*: Similar to traditional Space Invaders, Aliens features the player (avatar) in the bottom of the screen, shooting upwards at aliens that approach Earth, who also shoot back at the avatar. The player loses if any alien touches it, and wins if all aliens are eliminated. *Scoring*: 1 point is awarded for each alien or protective structure destroyed by the avatar, and  $-1$  point is given if the player is hit.

2) *Boulderdash*: The avatar must dig in a cave to find at least 10 diamonds, with the aid of a shovel, before exiting through a door. Some heavy rocks may fall while digging, killing the player if it is hit from above. There are enemies in the cave that might kill the player, but if two different enemies collide, a new diamond is spawned. *Scoring*: 2 points are awarded for each diamond collected, and 1 point every time a new diamond is spawned. Also,  $-1$  point is given if the avatar is killed by a rock or an enemy.

3) *Butterflies*: The avatar must capture butterflies that move randomly around the level. If a butterfly touches a cocoon, more butterflies are spawned. The player wins if it collects all butterflies, but loses if all cocoons are opened. *Scoring*: 2 points are awarded for each butterfly captured.

4) *Chase*: The avatar must chase and kill scared goats that flee from the player. If a goat finds another goat’s corpse, it becomes angry and chases the player. The player wins if all scared goats are dead, but it loses if it is hit by an angry goat. *Scoring*: 1 point for killing a goat and  $-1$  point for being hit by an angry goat.

5) *Frogs*: The avatar is a frog that must cross a road, full of trucks, and a river, only traversable by logs, to reach a goal. The player wins if the goal is reached, but loses if it is hit by a truck or falls into the water. *Scoring*: 1 point for reaching the goal, and  $-2$  points for being hit by a truck.

6) *Missile Command*: The avatar must shoot at several missiles that fall from the sky, before they reach the cities they are directed towards. The player wins if it is able to save at least one city, and loses if all cities are hit. *Scoring*: 2 points are given for destroying a missile and  $-1$  point for each city hit.

7) *Portals*: The avatar must find the goal while avoiding lasers that kill him. There are many portals that teleport the player from one location to another. The player wins if the goal is reached, and loses if killed by a laser. *Scoring*: 1 point is given for reaching the goal.

8) *Sokoban*: The avatar must push boxes so they fall into holes. The player wins if all boxes are made to disappear, and loses when the timer runs out. *Scoring*: 1 point is given for each box pushed into a hole.

Information	Description	Possible Values	Init	Act	End
<b>Game Information</b>					
<b>Score</b>	Score of the game.	$[0..N] \in \mathbb{N}$	✓	✓	✓
<b>Game tick</b>	Current game tick.	$[0..1000] \in \mathbb{N}$	✓	✓	✓
<b>Game winner</b>	Indicates the result of the game for the player.	$\{won, lost, ongoing\}$	✓	✓	✓
<b>Is game over</b>	Indicates if the game is over.	$\{true, false\}$	✓	✓	✓
<b>World's dimension (width)</b>	Width of the level (in pixels).	$[0..N] \in \mathbb{R}$	✓		
<b>World's dimension (height)</b>	Height of the level (in pixels).	$[0..N] \in \mathbb{R}$	✓		
<b>Block size (bs)</b>	Number of pixels each grid cell has.	$[0..N] \in \mathbb{N}$	✓		
<b>Actions Information</b>					
<b>Actions</b>	Available actions of the game.	A subset of $\{nil, up, down, left, right, use\}$	✓		
<b>Avatar Information</b>					
<b>Avatar position (x)</b>	$x$ coordinate (in pixels) of the avatar's position.	$[0..N] \in \mathbb{R}$	✓	✓	✓

<b>Avatar speed</b>	Speed of the avatar (pixels/tick).	$[0..N] \in \mathbb{N}$	✓	✓	✓
<b>Avatar last action</b>	Last action played by the avatar.	One of $\{nil, up, down, left, right, use\}$	✓	✓	✓
<b>Avatar resources</b>	Collections of pairs $\langle K, V \rangle$ , where $K$ is the type of resource and $V$ is the amount owned.	$\{\langle K_1, V_1 \rangle, \langle K_2, V_2 \rangle, \dots\}; K_i, V_i \in \mathbb{N}$	✓	✓	✓
<b>Grid Information (for each type of sprite)</b>					
<b>Sprite type</b>	Sprite identifier.	$[0..N] \in \mathbb{N}$	✓	✓	✓
<b>Grid Bitmap</b>	Presence array of the sprite type on the grid. 1 means presence, 0 means absence.	Array $\{0, 1\}$ of size $[width/bs, height/bs]$	✓	✓	✓

TABLE I: Information given to the controllers for action decision. The controller of the agent receives this information on the three different calls: *Init* (at the beginning of the game), *Act* (at every game cycle) and *End* (when the game is over). Pieces of information only sent on the *Init* call are constant throughout the game played.

9) *Survive Zombies*: The avatar must stay alive while being attacked by spawned zombies. It may collect honey, dropped by bees, in order to avoid being killed by zombies. The player wins if the timer runs out, and loses if hit by a zombie while having no honey (otherwise, the zombie dies). *Scoring*: 1 point is given for collecting one piece of honey, and also for killing a zombie. Additionally,  $-1$  point if the avatar is killed, or it falls into the zombie spawn point.

10) *Zelda*: The avatar must find a key in a maze to open a door and exit. The player is also equipped with a sword to kill enemies existing in the maze. The player wins if it exits the maze, and loses if it is hit by an enemy. *Scoring*: 2 points for killing an enemy, 1 for collecting the key, and another point for reaching the door with it.  $-1$  point is given if the avatar is killed.

In order to show the diversity of these games, Table II shows the features of each one of them. In this table, the *Score System* indicates how the reward is given to the avatar by means of a numeric score. This system can be either **binary** (B) or **incremental** (I). In the former case, the score of the game will always be 0 until victory is achieved, when the reward will become 1. In the latter scenario, points are regularly awarded throughout the course of the game.

In this table, the *Score System* indicates how the reward is given to the avatar by means of a numeric score. This system can be either **binary** (B) or **incremental** (I). In the former case, the score of the game will always be 0 until victory is achieved, when the reward will become 1. In the latter scenario, points are regularly awarded throughout the course of the game.

The second column, *NPC Types*, indicates the sort of other moving entities that can be found in the game. *Friendly* refers to those Non Player Characters (NPC) that do not harm the player, whereas *Enemies* refer to those NPCs that pose

some hazard in the game. Additionally, one game also features more than one type of enemies (*Boulderdash*).

*Resources* indicates if the game contains sprites that can be picked up by the player or not, and *Terminations* relate to how the game can end. A game can finish either by creating or destroying one or more sprites of a given type (column *Counters*), reaching a goal (*Exit Door*) or when a timer runs out (*Timeout*). Independently, all games can finish eventually (with a loss) if the maximum number of game steps that can be played, set to 1000 for all games, is reached. This limit is introduced in order to avoid degenerate players from never finishing the game.

Finally, each one of these games provides a different set of available actions to the player. Those games labelled in Table II as *a0* provide the complete set of actions ( $\{nil, up, down, left, right, use\}$ ). *A1* games are those where the actions are only directional (this is, the complete set without the *use* action). Finally, *A2* indicates the subset composed by  $\{nil, left, right, use\}$ .

It is worthwhile highlighting that the variety of these games poses a serious hazard to the playing agents. The learning algorithm needs to learn how the game has to be played in order to achieve victory and maximize score. It is important to realize that the description of the game is not passed to the agent at any time, thus the only way the agent can learn how to play the game is to analyze the game state (maybe by extracting features) and build relations between the observations and the games played.

Of course, one could try to identify the game that is being played and act consequently. However, this is of a limited research interest, as the long term objective is to find agents that can learn any game (rather than building an agent that uses a database of known games, heuristically prepared to play these). Figure 1 shows screenshots of four of the games employed in this research.

Game	Score System	NPC Types			Resources	Terminations			Action Set
		Friendly	Enemies	> 1 type		Counters	Exit Door	Timeout	
Aliens	I		✓			✓			A2
Boulderdash	I		✓	✓	✓		✓		A0
Butterflies	I	✓				✓			A1
Chase	I	✓	✓			✓			A1
Frogs	B						✓		A1
Missile Command	I		✓			✓			A0
Portals	B						✓		A1
Sokoban	I					✓			A1
Survive Zombies	I	✓	✓		✓			✓	A1
Zelda	I		✓		✓		✓		A0

TABLE II: Games feature comparative. All games of the competition are listed, divided into the 3 game sets: training (first 10), validation (next 10) and test (last 10). Legend: I: Incremental; B: Binary; A0: All moves; A1: Only directional; A2: Left, right and use. Check Section III-B for a full description of the meaning of all terms in this table.

Fig. 1: Four of the ten training set games: from top to bottom, left to right, *Butterflies*, *Portals*, *Sokoban* and *Zelda*.

#### IV. APPROACHES

##### A. Learning Algorithms

As stated in the introduction we coupled two different kinds of function approximators with two different exploration policies and evolved the weights. Assuming input features  $\phi$  and a set of action  $mA$  we evolved a set of weights for each action  $w_a$ :

- $p_a^{linear} = w_a^0 \cdot \phi$  for the linear function approximator,
- $p_a^{nn} = w_a^0 \cdot \max w_1 \cdot \phi, 0$  for the rectifier neural network [13]

The types of exploration used are softmax and e-greedy. We normalise all inputs on the function approximators incremental between -1 and 1. Notice that the output layer of weights  $w_a^0$

for the neural network approximator is the same for all actions and set to 20 (i.e., the total number of hidden neurons). Using  $p_a$  we define two different policies

- $\pi^\epsilon(\phi, a) = \begin{cases} 1 - \epsilon + \epsilon/|A| & \text{if } a = \arg \max_{a \in A} p_a \\ \epsilon/|A| & \text{otherwise} \end{cases}$
- $\pi^{softmax}(\phi, a) = e^{p_a} / \sum_{b \in A} p_b$

All the possible combinations of policies and function approximators are used in the experiments. Training the function approximators involves learning the weights  $w$ . We use Separable Natural Evolution Strategies (S-NES) for this [4]. Since we used 7 features for each action, and GVG-AI supports 4 actions, we would have a 28 dimensional problem for the linear approximator and a 220 dimensional problem for the

neural network approximator.

S-NES is an evolution strategy that learns that follows the natural gradient (which can be seen as a gradient that uses KL-divergence between as a measure of distance instead of euclidean distance). It assumes that the search parameters come from a multi-variate Gaussian distribution and tries to adapt the Gaussian’s mean and covariance-matrix using the natural gradient. A transformation on the fitness structure of the problem also takes place; using a populations of samples, the fitness is transformed to  $[0, 1]$  using a ranking scheme, which makes the algorithm invariant to transformations of the target function as long as these transformations do not impact ranking order. The “Seperable” element of the algorithm used here refers to adapting only the diagonal elements of the covariance matrix. This speeds up learning significantly, allowing the S-NES to scale linearly to problems of arbitrary size (instead of quadratically).

### B. Game features

All algorithms employed in this experimental study use the same set of features for learning. These features are extracted from the game state, which is received in the format explained in Section III-A and Table I. The features employed in this research are all numeric, and detailed next:

- Game score.
- Game tick.
- Game winner (−1 if game is still ongoing, 0 if the player lost and 1 if the player won).
- Game over (1 if game is over, 0 otherwise).
- Resources: list of the amount of resources owned by the avatar<sup>1</sup>
- List with the Euclidean distances to the closest sprite of each type.
- Speed of the avatar.

## V. EXPERIMENTS

The algorithms proposed in the previous section have been tested in the games described previously in Section III-B. For each one of the 10 present games, the first available level has been used for a learning process where each algorithm played 1000 consecutive times. For each game, 50 experiments where run, and the average of the progression of the score is plotted in Figures 2 and 3.

This figure shows the average of score, including the standard error (shadowed area), as it progresses with the number of matches, for each one of the games played. The first aspect to realize is that learning can be appreciated in 8 out of the 10 games employed in the experimental study. It is not possible to declare any of the algorithms as an overall best option, as it general depends on the game played.

It seems clear that in some games (such as *Aliens*, *MissileCommand* or *SurviveZombies*) the algorithms with an  $\epsilon$ -greedy policy learn better, while in others (such as *Frogs* or *Zelda*) it is the algorithms with a *Softmax* policy the ones

with a better performance. For instance, in the game *Frogs*,  $\epsilon$ -greedy algorithms are not able to survive (a score of −2 reflects that the player is killed by a truck), while *Softmax* approaches are capable to learn how to avoid these. Regarding the approximations used, even when the difference is small, the results suggest that the linear approximator works better than the neural network, for both policies tested and most of the games. A possible explanation for this is that the neural network operates in a larger search space, which can potentially inhibit its learning capabilities in the short term.

The cases where learning cannot be achieved by any of the algorithms tested here happen in the games *Portals* (where the score is 0 through the whole process) and *Sokoban* (with an interesting jagged curve). The low performance of all algorithms in these two games can be due to different reasons.

In the case of *Portals*, the game requires a long sequence of movements (traversing portals) before reaching the goal, which is the only moment where the agent receives positive feedback. As reaching the exit is extremely unlikely, the flat landscape of rewards avoids the agent from learning how to score points in the game. Interestingly, the hazards in the game that kill the player are well avoided in general. The results show that the time spent in the game (not depicted due to lack of space) is close to 60 and 100% of the maximum time allowed (for algorithms with  $\epsilon$ -greedy and *Softmax* policies, respectively). This means that the algorithms, specially the ones with a *Softmax* policy, are able to learn very quickly how to survive in this game, albeit ending with a score of 0.

An explanation for the strange results on *Sokoban* may be related to the features used for learning. In this game, score is achieved when a box is introduced into a hole in the level. With the features extracted from the game state (see Section IV-B), this can be related to minimizing distances between avatar and the closest box, and between the avatar and the closest hole. The problem is that these minimizations must happen simultaneously, and with the avatar pushing the box in the right direction and when a hole is at the other side. These situations happen rarely, and it is reflected in this game’s plot with picks along the curve. As the features only allow the algorithms to determine distances (and not the supplementary needed requirements), they are not able to learn properly and performance decreases. The game of *Sokoban* has been traditionally one of the most difficult ones from the GVGA framework and competition [6].

It is also worthwhile highlighting that in some games, after the 1000 matches, the improvement on the score average has not stopped, what suggest that better results can be found with longer execution trials.

## VI. CONCLUSIONS

This paper shows a first comparison of different policies ( $\epsilon$ -greedy and *Softmax*) and function approximators, using an evolutionary algorithm (S-NES) as learning scheme. The objective of the agents that implement these algorithms is to learn how to maximize the score in ten different games, without the help of any domain knowledge that indicates how this can be achieved. Additionally, all these games have different characteristics, which allows to examine in what conditions learning is performed better.

<sup>1</sup>In order to have a fixed number of features, the length of this list is set to 5 (the number of avatar resources can vary from game to game, from none to  $N$  types).

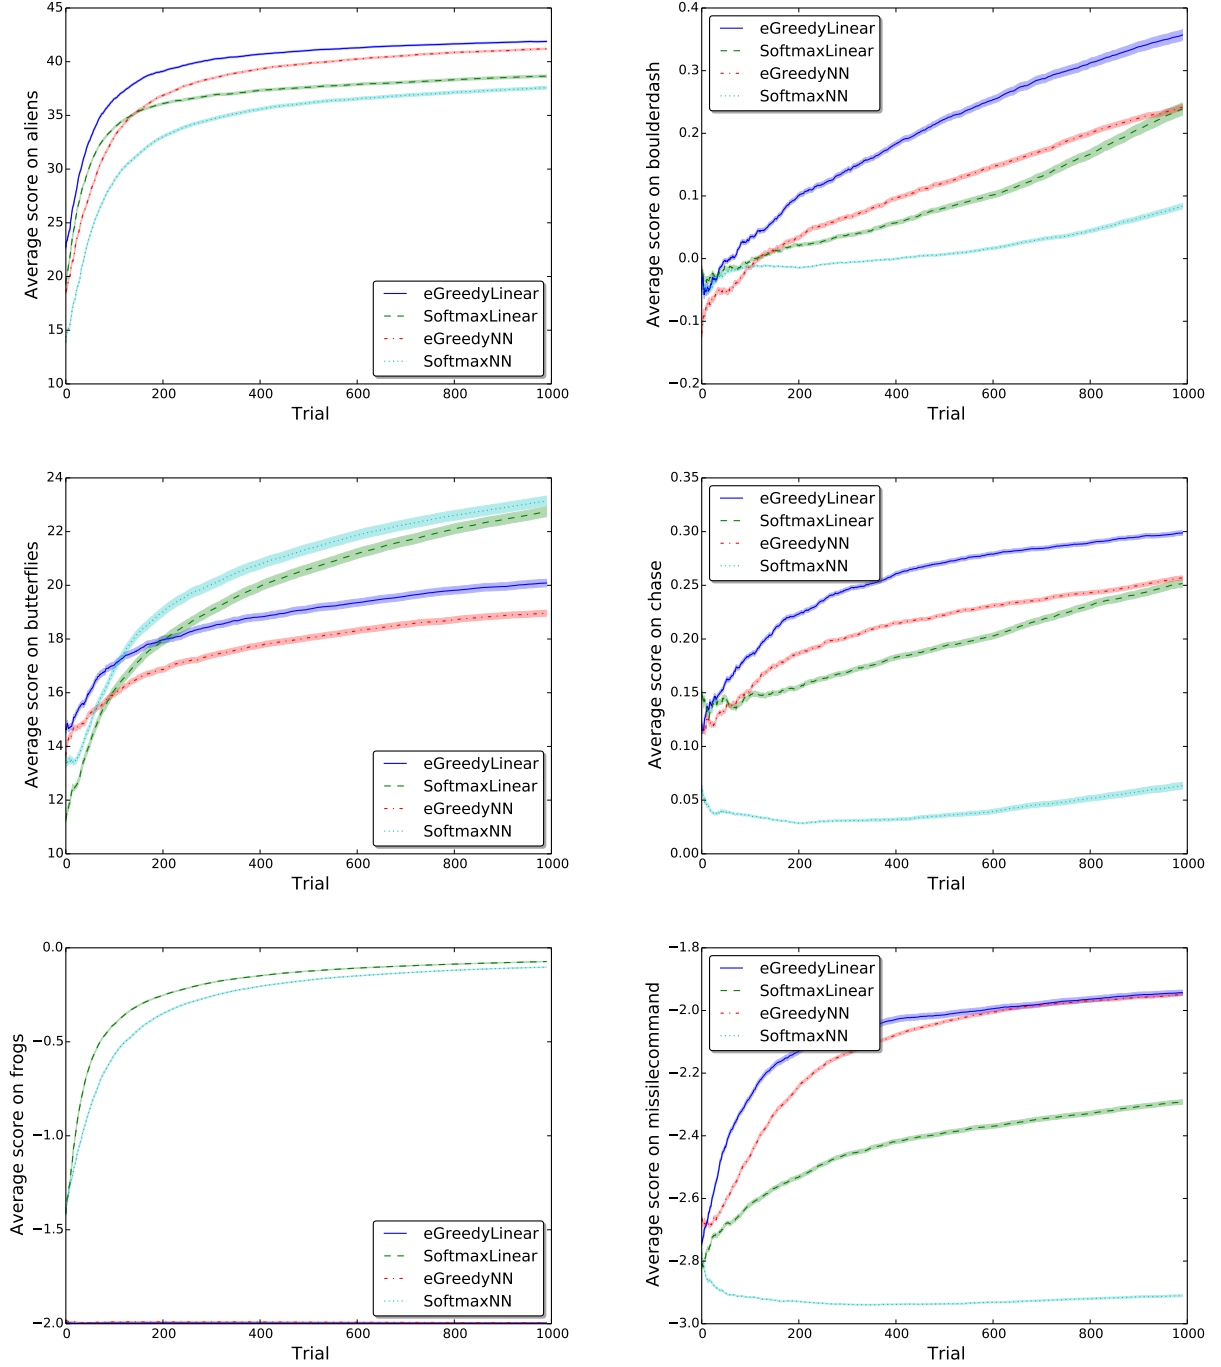

Fig. 2: Progression of the average score during 1000 trials. Horizontal axis denotes the trial, while vertical axis shows the average score. Shaded area indicates the standard error of the measure. From left to right, top to bottom, the games are *Aliens*, *Boulderdash*, *Butterflies*, *Chase*, *Frogs* and *MissileCommand*.

In this study, the algorithms tested are able to learn in most of the games tested. In particular, linear function approximators seem to perform best in this setup.

Although the robustness of evolutionary computation is commendable, it might be worth attacking the same problems using more traditional, gradient-based approaches (e.g. Monte

Carlo methods, SARSA/Q Learning). This would allow for the training of deeper networks which could possibly help. This could be coupled without using features at all, but rather using the raw bitplanes as input. It is also obvious that more training would be very beneficial for a number of games.

Finally, an important point to make here is that effectively

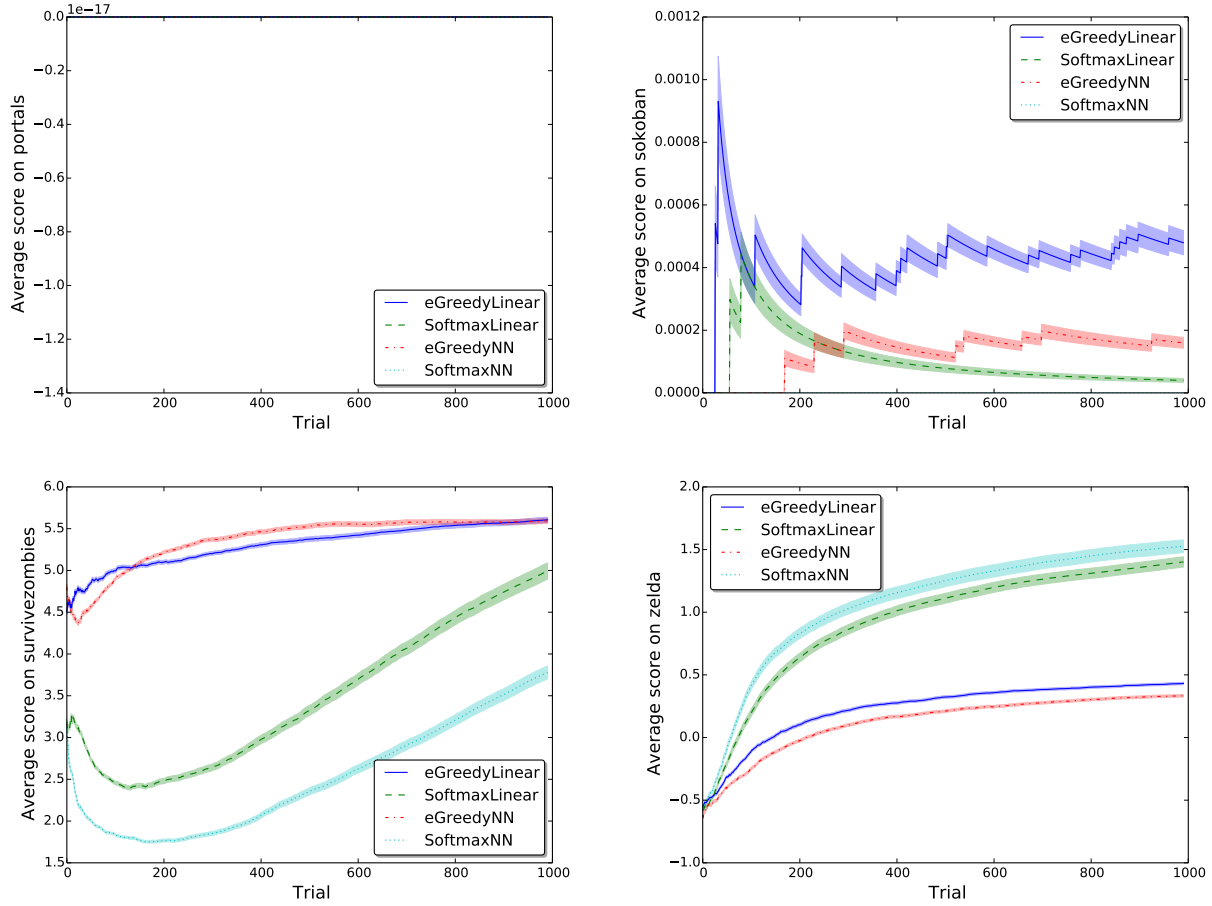

Fig. 3: Progression of the average score during 1000 trials. Horizontal axis denotes the trial, while vertical axis shows the average score. Shaded area indicates the standard error of the measure. From left to right, top to bottom, the games are *Portals*, *Sokoban*, *SurviveZombies* and *Zelda*.

testing and learning are happening on the same levels; if we are to see generalisational abilities different levels should be used for testing for each game.
